Abstract

The paper modifies the methodology of Simar and Wilson 2007 [J Econometrics 136] and 1998 [Manage Sci 44] to propose a new algorithm for robust estimation of cost efficiency in data envelopment analysis in terms of bias correction and estimating returns to scale. Simulation analyses with multi-input multi-output Cobb-Douglas production function with correlated outputs, and correlated technical and cost efficiency demonstrate consistency of the new algorithm both in absence and presence of environmental variables. Finally, we offer real data estimates for Japanese banking industry.

An R package ‘rDEA’, developed for computations, is available from GitHub and CRAN repository.

Keywords: data envelopment analysis, cost efficiency, bias correction, bootstrap

JEL Classification Codes: C440, C610

1 Introduction

Data envelopment analysis (DEA) (Charnes et al. (1978)) is a linear optimization technique, stemming from the seminal work of Farrell (1957), who suggested definitions of technical and price efficiency of a firm, based on its distance from the frontier of efficient firms. However, the empirical frontier is constructed according to a given sample of observations, and therefore, the DEA efficiency scores, that are linked to the empirical frontier, are biased. A homogeneous bootstrap based on re-sampling from a smooth consistent estimator of the joint density of input-output pairs (Simar and Wilson (2000b); Simar and Wilson (1998)) or semi-parametric bootstrap in presence of environmental variables (Simar and Wilson (2007)) became standard approaches 1 for consistent correction of the bias of technical efficiency scores (Simar and Wilson (2011b); Kneip et al. (2008)). As regards cost efficiency scores (Fare et al. (1985)), practitioners suggests using a direct modification of Simar and Wilson (1998) and Simar and Wilson (2007) bootstrap (de Borger et al. (2008)). However, in this paper we show that the direct modification is inconsistent and propose an alternative bootstrap algorithm. To estimate the bias the proposed algorithm re-samples “naive” input-oriented efficiency scores, rescales original inputs to bring them to the frontier, and then re-estimates cost efficiency scores for the rescaled inputs. The new algorithm is also applied to estimating returns to scale in case of cost minimization DEA. The results of the simulations for multi-input multi-output Cobb-Douglas production function with correlated outputs, and correlated technical and cost efficiency, show consistency of our proposed algorithm in terms of coverage probability of Kneip et al. (2008) confidence intervals for true cost efficiency, even for small samples. As regards returns to scale test, our simulations show that Simar and Wilson’s (2011b, 2002) statistics are applicable for cost minimization analysis. As for a recently defined “new” cost efficiency (Tone (2002)), which to the best of our knowledge is commonly assessed only in terms of naive scores, we demonstrate that the direct modification of Simar and Wilson (1998) and Simar and Wilson (2007) bootstrap is consistent. Our estimations are conducted with an R package ‘rDEA’ (Simm and Besstremyannaya, 2014), which is available from GitHub and CRAN repository.

The remainder of the paper is structured as follows. Section 2 sets up microeconomic framework for existence of technical and cost inefficiencies. Section 3 reviews theoretical framework for bias correction of technical efficiency scores (using an example of input orientation). Section 4 demonstrates inconsistency of a direct application of Simar and Wilson (1998) or Simar and Wilson (2007) bootstrap and offers an alternative bootstrap algorithm for robust estimation of Fare et al. (1985) cost efficiency in absence (presence) of environmental variables. Section 5 conducts simulations for various data generating processes for production frontier and technical and cost inefficiencies. Section 6 provides real data estimates with a sample of 112 Japanese banks in fiscal year 2009.

2 Estimates of input-oriented efficiency

2.1 Naive score

Denote the existing technology, which produces outputs $y_m$ ($m = 1,...,M$) using inputs $x_n$ ($n = 1,...,N$) as $T = \{(x, y) : x \geq X\lambda, y \leq Y\lambda, \lambda \geq 0\}$. Input set $L(y)$ (Coelli et al. (1994); Shephard (1981)) contains inputs, that can produce a given amount of output under $T$, so that $L(y) = \{(x) : (x, y) \in T\}$. The important assumptions are strict convexity of $L(y)$ and strong (free) disposability of inputs and outputs. In particular, strong disposability of inputs implies that if $x \in L(y)$, and if $x' \geq x$, then $x' \in L(y)$. The input-oriented efficiency $\theta_j$ for a given decision making unit (DMU) $j$ ($j = 1,...,J$) is defined as a solution

1In absence of environmental variables, the smooth bootstrap provides better inference in non-simulation context (Kneip et al. (2008)) than an alternative bootstrap based on subsampling (Simar and Wilson (2011a))
to the below optimization problem (for constant returns to scale, CRS, Charnes et al. (1978)):

$$\min_{\theta_j, \lambda_j} \theta_j$$

s.t. $-y_{mj} + \sum_{i=1}^{J} \lambda_i y_{mi} \geq 0, \quad m = 1, \ldots, M,$

$$\theta_j x_{nj} - \sum_{i=1}^{J} \lambda_i x_{ni} \geq 0, \quad n = 1, \ldots, N,$$

$$\lambda_i \geq 0, \quad i = 1, \ldots, J.$$  

(1)

Additional constraints $\sum_{i=1}^{J} \lambda_i x_{ni} = 1$ impose variable returns to scale (VRS).

2.2 Bias correction

The estimates of input-oriented efficiency are upwards biased, since the estimated boundary $\hat{L}_i(y)$ of the input set is based on the sample of the observed DMUs, which may fail to incorporate the most efficient DMUs in the true $L(y)$ (Simar and Wilson (1998); Simar and Wilson (2000a)). Therefore, the bootstrap methods correct for the bias, constructing pseudo-samples which would belong to $\hat{L}(y)$. Then, according to the re-centering idea of bootstrap, for each DMU $i$ bias $\theta_i = \hat{E}(\hat{\theta}_i) - \hat{\theta}_i = \text{bias} \hat{\theta}_i = \text{bias} \hat{\theta}_i^* = \hat{E}(\hat{\theta}_i^*) - \hat{\theta}_i$. In particular, the homogeneous smoothed bootstrap projects each observation on the frontier and then “pushes” it inside the $\hat{L}(y)$ (Simar and Wilson (2008); Simar and Wilson (1998)).

1. Estimate naive scores $\hat{\theta}_1, \ldots, \hat{\theta}_J$, for each $i = 1, \ldots, J$ according to system (1). Assume $(\theta_1, \ldots, \theta_J)$ are i.i.d. with pdf $f(\cdot)$.

2. Loop $B$ times to obtain $J$ sets of bootstrap estimates $\{\hat{\theta}_i^*\}_{b=1}^{B}$.

2.1 Obtain a smooth estimate $\hat{f}(\theta)$ and for each $i = 1, \ldots, J$ draw $\theta_i^*$ from this estimate.\(^2\)

2.2 Assume homogeneous distribution of joint density of $\theta$ in input-output space, i.e. $\hat{f}(\theta_i|(x_i, y_i)) = \hat{f}(\hat{\theta}_i)$ and assign $x_i^* = \frac{\hat{\theta}_i}{\theta_i^*} x_i$.

2.3 Calculate $\hat{\theta}_i^*$ for $(x_i^*, y_i)$.

3. $\hat{\text{bias}} \hat{\theta}_i = \frac{1}{B} \sum_{b=1}^{B} \hat{\theta}_i^* - \hat{\theta}_i$ and bias-corrected score $\hat{\theta}_i = \hat{\theta}_i - \hat{\text{bias}} \hat{\theta}_i$.

Rescaling at step (2.2) guarantees that pseudo-samples $\{(x_i^*, y_i)\}_{b=1}^{B} \in \hat{L}(y)$. Indeed, input-oriented efficiency evaluates the potential of DMU $i$ for maximal reduction of inputs, holding the amount of outputs constant. The constraints $x_i \geq X \lambda$ imply inputs are larger than possible. Therefore, multiplications of each input by $\hat{\theta}_i$, $0 \leq \hat{\theta}_i \leq 1$, projects it to $\hat{L}(y)$, so that the projected observation become an estimate of an efficient input level with coordinates $(\hat{\theta}x_i, y_i)$. The assumption about homogeneous distribution of joint density of $\theta$ allows drawing each $\theta_i^*$ for pseudo-samples from the same estimate of $\hat{f}(\theta)$, which is obtained for the original sample. Therefore, division of each projected input by $\theta_i^*$, $0 \leq \theta_i^* \leq 1$ in step (2.2) “pushes” the projected input inside $\hat{L}(y)$.

\(^2\)Smoothing is necessary to avoid inconsistency in estimating the upper bound of the support of the underlying data-generating process $f(\cdot)$ (Simar and Wilson (1998)).
In presence of an $r$-dimensional vector of *environmental* variables $z$ (i.e. a special type of inputs that are not directly controlled by producers) Simar and Wilson (2007) propose semi-parametric bootstrap for correcting the bias of distance function score $δ$, the reciprocal of $θ$. The algorithm, in case of input-orientation, is based on the premise about the separability of inputs and environmental variables, i.e. the fact that the support of $x$ does not depend on $z$ (Simar and Wilson (2011b)).

1. Estimate naive distance function scores $\hat{δ}_1, ..., \hat{δ}_J$, for each $i = 1, ..., J$ using the equivalent of system (2) for reciprocals of $θ$. Assume $\hat{δ}_i = z_i \beta + ε_i ≥ 1$, where $ε_i$ are i.i.d. and independent from $z_i$, $ε_i \sim N(0, σ^2_ε)$ with left truncation at $(1 - z_i \beta)$.

2. Use observations for which $\hat{δ} > 1$ to obtain $\hat{β}$ and $\hat{σ}_ε$ in the truncated regression $\hat{δ}_i = z_i \hat{β} + ε_i ≥ 1$.

3. Loop $B$ times to obtain $J$ sets of bootstrap estimates $\{\hat{δ}^*_{ib}\}_{b=1}^B$.
   3.1 For each $i = 1, ..., J$ draw $ε_i$ from $N(0, \hat{σ}^2_ε)$ with left truncation at $(1 - z_i \hat{β})$.
   3.2 For each $i = 1, ..., J$ compute $\hat{δ}^*_i = z_i \hat{β} + ε_i$.
   3.3 Assign $x^*_ib = \frac{\hat{δ}^*_i}{\hat{δ}_i} x_i$.
   3.4 Calculate $\hat{δ}^*_ib$ for $(x^*_ib, y_i)$.

4. $\hat{\text{bias}}_i = \frac{1}{B} \sum_{b=1}^B \hat{δ}^*_ib - \hat{δ}_i$ and bias-corrected score $\hat{δ} = \hat{δ} - \hat{\text{bias}}$.

### 2.3 Returns to scale

The above algorithm consistently estimates the sampling distribution of the original efficiency scores and therefore, is applicable for testing returns to scale (Simar and Wilson (2002)). For instance, the null hypothesis of constant returns to scale versus an alternative hypothesis of variable returns to scale may be tested through bootstrapping an appropriate test statistics under the null hypothesis (Simar and Wilson (2011b), Simar and Wilson (2008), Simar and Wilson (2002)). The simulation analyses show that statistics equal to the ratio of mean scores $\frac{\sum_{j=1}^J θ_{CRS}(x_i, y_i)}{\sum_{j=1}^J θ_{VRS}(x_i, y_i)}$ provides for tests of good power (Simar and Wilson (2002)). Yet, the most appropriate test statistics, stemming from the theoretical result in Kneip et al. (2008) is the mean of ratios $\frac{1}{J} \sum_{j=1}^J θ_{CRS}(x_i, y_i)/θ_{VRS}(x_i, y_i)$ (Simar and Wilson (2011b)).

---

$^3$θ, which is bounded between 0 and 1, could not be used for computational reasons in estimating truncated regression (Simar and Wilson (2008)).
3 Estimates of cost efficiency

3.1 Naive score with given input prices

Denote \( w_j \) the vector of input prices. Fare et al. (1985) define cost efficiency \( \gamma_j \) as

\[
\gamma_j = \frac{w_j x_{j,\text{opt}}}{w_j x_j}
\]  

where \( x_{j,\text{opt}} \) is a solution to the optimization problem (formulated below for constant returns to scale):

\[
\min_{x_j, \lambda} w_j x_j \\
\text{s.t.} \\
- y_m j + \sum_{i=1}^{I} \lambda_i y_{mi} \geq 0, \quad m = 1, \ldots, M, \\
-x_n j - \sum_{i=1}^{I} \lambda_i x_{ni} \geq 0, \quad n = 1, \ldots, N, \\
\lambda_i \geq 0, \quad i = 1, \ldots, J.
\]

According to (2) and system(3), \( 0 \leq \gamma_j \leq 1 \) by construction. Note that eq.(3) assumes that producers face input prices as given.

3.2 Proposed bootstrap algorithm: Fare et al. (1985) cost efficiency

Similarly to input-oriented efficiency scores, Fare et al. (1985) cost efficiency scores are linked to \( \hat{L}_\theta(y) \) and therefore, are upwards-biased. Yet, a direct modification of Simar and Wilson (1998) (Simar and Wilson (2007)) algorithm to bias correction of cost efficiency score \( \gamma \), which simply replaces \( \theta \) by \( \gamma \) at steps 2.2 (step 3.3) (de Borger et al. (2008)), is inconsistent. Indeed, let’s look at a given observation \( i \) with coordinates \( x_i \) (point \( P \) at Figure (2)). By definition of input-oriented efficiency, point \( P'' \), which is an intersection of the ray from the origin to \( P \) and \( \hat{L}_\theta(y) \), has coordinates \( \hat{\theta} x_i \). The hyperplane, set by the cost function \( w_j x_j \) and tangent to \( \hat{L}_\theta(y) \), intersects the ray from the origin to point \( P \) at point \( P' \). Since points \( P^* \) and \( P' \) are on the same hyperplane, the costs in these points are equal. Therefore, by definition of cost efficiency score, point \( P' \) has coordinates \( \hat{\gamma} x_i \). Consequently, point \( P'' \), obtained through rescaling inputs by \( \hat{\gamma}_i / \hat{\gamma}_{i,b} \), belongs to \([P', P]\). However, it may happen that \( P'' \notin [P', P] \), i.e. \( P'' \notin [P', P'] \). So the vector of bootstrapped inputs, obtained at step 2.2 of a direct modification of Simar and Wilson (1998) algorithm, may be outside the \( \hat{L}_\theta(y) \).

(The same argument applies to step (3.3) for the case with environmental variables, where \( \hat{\theta} = \hat{\theta}(z_i) \) and \( \hat{\gamma} = \hat{\gamma}(z_j') \)). Note that the assumptions about strict convexity of \( L(y) \) and free disposability of inputs are importantly exploited in our argument.

Instead, to correct for the bias of Fare et al. (1985) cost efficiency we propose the following bootstrap, which is homogeneous both in terms of \( f_\theta(\cdot) \) and \( f_\gamma(\cdot) \) and constructs pseudo-samples through re-sampling the input-oriented technical efficiency score and rescaling original inputs by the ratio \( \hat{\theta}_i / \hat{\theta}_{i,b} \). In this way, the bootstrapped inputs are “pushed” inside the \( \hat{L}_\theta(y) \). Therefore, \( \hat{\gamma}_{i,b}' \), which calculated for the bootstrapped inputs at step (4) of our algorithm, allow for consistent bias correction:

1. Estimate naive cost efficiency scores \( \hat{\gamma}_1, \ldots, \hat{\gamma}_J \) for each \( i = 1, \ldots, J \). Assume \((\hat{\gamma}_1, \ldots, \hat{\gamma}_J)\) are i.i.d. with pdf \( f_\gamma(\cdot) \).

2. Estimate naive input-oriented efficiency scores \( \hat{\theta}_1, \ldots, \hat{\theta}_J \). Assume \((\hat{\theta}_1, \ldots, \hat{\theta}_J)\) are i.i.d. with pdf \( f_\theta(\cdot) \).
3. Obtain $\theta^*_b$ through smoothed bootstrap, and under the assumptions of homogeneous distribution of joint density of $\theta$ and joint density of $\gamma$ in input-output space, assign $x^*_b = \frac{\partial}{\partial x_i} F_i (b = 1, ..., B)$.

4. Calculate $\hat{\gamma}^*_b$ for $(x^*_b, y_i)$.

5. For each $i$, bias $\hat{\gamma}_i = \frac{1}{B} \sum_{b=1}^{B} \hat{\gamma}^*_b - \hat{\gamma}_i$.

In presence of the environmental variables, given Simar and Wilson (2007) assumption about separability of $x$ and $z$ (i.e. the fact that $L^\gamma(y)$ does not depend on $z$), we propose the following algorithm for the reciprocal of Fare et al. (1985) cost efficiency score, denoted $\delta^\gamma_i$:

1. Estimate reciprocals of naive cost efficiency scores $\hat{\delta}^\gamma_1, ..., \hat{\delta}^\gamma_J$, for each $i = 1, ..., J$ using system (3). Assume $\delta^\gamma_i = z^\gamma_i \beta^\gamma + \psi_i \geq 1$, where $\psi_i$ are i.i.d. and independent from $z^\gamma_i$, $\psi_i \sim N(0, \sigma^2_\psi)$ with left truncation at $(1 - z^\gamma_i \beta^\gamma)$.

2. Estimate naive input-oriented distance function scores $\hat{\delta}_1, ..., \hat{\delta}_J$, for each $i = 1, ..., J$, using the equivalent of system (2) for reciprocals of $\theta$. Assume $\delta_i = z_i \beta + \epsilon_i \geq 1$, where $\epsilon_i$ are i.i.d. and independent from $z_i$, $\epsilon_i \sim N(0, \sigma^2_\epsilon)$ with left truncation at $(1 - z_i \beta)$.

3. Use observations for which $\hat{\delta} > 1$ to obtain $\hat{\beta}$ and $\hat{\sigma}_\epsilon$ in the truncated regression $\hat{\delta}_i = z_i \beta + \epsilon_i \geq 1$

4. Loop $B$ times to obtain $J$ sets of bootstrap estimates $\{\hat{\delta}_{ib}^\gamma\}^B_{b=1}$.

4.1 For each $i = 1, ..., J$ draw $\epsilon_i$ from $N(0, \hat{\sigma}^2_\epsilon)$ with left truncation at $(1 - z_i \hat{\beta})$.

4.2 For each $i = 1, ..., J$ compute $\delta^*_i = z_i \hat{\beta} + \epsilon_i$.

4.3 Given the semi-parametric dependence of $\delta$ on $z$, assign $x^*_ib = \frac{\partial}{\partial x_i} \delta^*_b x_i$.

4.4 Calculate $\hat{\delta}^\gamma_{ib}$ for $(x^*_ib, y_i)$.

5. Owing to semi-parametric dependence of $\delta^\gamma$ on $z^\gamma$, we can compute $\text{bias} \hat{\delta}^\gamma_i = \frac{1}{B} \sum_{b=1}^{B} \delta^*_b - \hat{\delta}^\gamma_i$ and $\hat{\delta}^\gamma = \hat{\delta}^\gamma - \text{bias} \hat{\delta}^\gamma$.

Note that $\{z_i\} \subset \{z^\gamma_i\}$. Indeed, as one of the reasons for the bias of cost efficiency scores is the bias of input-oriented scores (owing to the empirical estimate of the frontier), the list of predictors for $\delta^\gamma$ includes the list of predictors for $\delta$.

Figure 1: Bias correction of Fare et al. (1985) cost efficiency, isoquant in the two-input space
3.3 Proposed returns to scale test in Fare et al.’s (1985) cost minimization DEA

Since our proposed bootstrap algorithm consistently estimates the sampling distribution of the original cost efficiency scores under correctly specified returns to scale, it may be applicable for testing returns to scale for the production possibility frontier in cost minimization DEA.

Namely, in each bootstrap loop we first, conduct estimates with input-oriented efficiency under the null hypothesis and rescale inputs. Second, we compute cost efficiency scores \( \delta_{\gamma}^{\text{VRS}} \) for rescaled inputs under the null and alternative hypotheses and get the values of the test statistics \( \frac{1}{J} \sum_{j=1}^{J} \delta_{\gamma}^{\text{VRS}}(x_i, y_i) / \delta_{\gamma}^{\text{CRS}}(x_i, y_i) \) (Simar and Wilson (2011b)).

Note that our cost-minimization procedure relies on an input-oriented model. In other words, the necessary condition for the presence of constant returns to scale in the cost-minimization model is the non-rejection of the CRS hypothesis both in the RTS test for an input-oriented model and for cost-minimization model.

3.4 Naive cost efficiency score with input prices under producer control

Tone (2002) concentrates on input costs, assuming that producers may choose prices for their inputs.

Let \( \bar{x}_j = (w_{1j}x_{1j}, \ldots, w_{N_j}x_{N_j})^T \), \( \bar{X} = (\bar{x}_1, \ldots, \bar{x}_J)^T \), where \( w_j \) is a vector of prices for each input \( x_j \).

“New” cost efficiency for DMU \( j \) is defined as

\[
\bar{\gamma}_j = \frac{e\bar{x}_j^{\text{opt}}}{e\bar{x}_j} \tag{4}
\]

with \( \bar{x}_j^{\text{opt}} \) a solution to (constant returns to scale formulation):

\[
\min_{\bar{x}_j, \lambda} e\bar{x}_j \quad \text{s.t.} \quad -y_{mj} + \sum_{i=1}^{J} \lambda_i y_{mi} \geq 0, \quad m = 1, \ldots, M, \\
\bar{x}_{nj} - \sum_{i=1}^{J} \lambda_i \bar{x}_{ni} \geq 0, \quad n = 1, \ldots, N, \\
\lambda_i \geq 0, \quad i = 1, \ldots, J. \tag{5}
\]

Here \( e \) is a unit vector, and by construction in (4) and (5), \( 0 \leq \bar{\gamma}_j \leq 1 \).

3.5 Proposed bootstrap algorithm: Tone (2002) new cost efficiency

Denote \( T_n \) technology in Tone (2002) “new” technical (and cost) efficiency estimates.

\[
T_n = \{(\bar{x}, y) : \bar{x} \geq X\lambda, y \leq Y\lambda, \lambda \geq 0\}. \tag{6}
\]

Define the “new” input set \( L_n(y) = \{(\bar{x}) : (\bar{x}, y) \in T^n\} \). As is demonstrated in Tone (2002) (theorem 4), the set of constraints on each \( \bar{x}_{nj} \) in (5) is equivalent to the below aggregate constraint:

\[
e\bar{x} - eX\lambda \geq 0 \tag{7}
\]

Consequently, for a given level of \( y \), the \( \bar{L}_n(y) \) is a hyperplane, parallel to the hyperplane set by a given level of the objective function \( e\bar{x}_j \). Therefore, the tangency of the objective function and \( \bar{L}_n(y) \) implies that the
two hyperplanes are coincident (Figure 2). Accordingly, the ray from origin to the point \( P \in \hat{L}_n(y) \) intersects \( \hat{L}_o(y) \) and the hyperplane, set by the objective function, at the same point. So \( P' = P''' \). In other words, as is noted in Tone (2002) (theorem 6), the “new” cost efficiency point is also “new” technically efficient.\(^4\) So a consistent bias correction of Tone (2002) “new” cost efficiency score may be conducted through a direct application of Simar and Wilson (1998) (Simar and Wilson (2007)) algorithm, so that the following rescaling is implemented at step (3) (step (3.3)): \( \bar{x}_{i,b} = \frac{\bar{\gamma}}{\gamma_{i,b}} \bar{x}_i \). Indeed, as \( L_0^o(y) \) is set by the aggregate constraint (7), \( P'' \in [P', P] \) is equivalent to \( P''' \in [P''', P'] \). Therefore, rescaling guarantees that each component of \( \bar{x}_b \) is larger than the corresponding component of the original vector \( \bar{x} \), and vector \( \bar{x}_b \) lies in the necessary subspace relative to \( L_0^o(y) \) (Besstremyannaya (2013)).

4 Simulations

4.1 Methodological framework

The Cobb-Douglas production function, commonly used in the non-parametric efficiency analysis in the banking industry (Kneip et al. (2011); Fethi and Pasiorras (2010); Thanassoulis et al. (2008); Kneip et al. (2008); Badin and Simar (2003); Simar and Wilson (2002); Simar and Wilson (2000b); Kittelsen (1999); Banker et al. (1993)) is taken in the form (Kumbhakar (2011); Resti (2000))

\[
y_m = A_m \prod_{n=1}^{N} x_{nm}^{\alpha_{nm}},
\]

where \( x_{nm} \) is the quantity of \( n \)-th input, used to produce \( m \)-th output (\( x_n = \sum_{m=1}^{M} x_{nm} \)). \( A_m \) and \( \alpha_{nm} \) are the parameters. Outputs \( y_m \) and input prices \( w_n \) are assumed to come from multivariate lognormal distributions, where vectors of means and variance-covariance matrices are taken from our real banking data (cases one and two with outputs from asset and intermediation approach, respectively).

\[
\text{Case one: } \ln(y) \sim N \left( \begin{bmatrix} 7.36 \\ 6.31 \end{bmatrix}, \begin{bmatrix} 1.2776 & 1.4743 \\ 1.4743 & 1.8293 \end{bmatrix} \right), \text{ case two: } \ln(y) \sim N \left( \begin{bmatrix} 3.65 \\ 2.33 \end{bmatrix}, \begin{bmatrix} 1.1668 & 1.4327 \\ 1.4327 & 1.9782 \end{bmatrix} \right).
\]

In both cases \( \ln(w) \sim N \left( \begin{bmatrix} 4.92 \\ -0.36 \\ -5.57 \end{bmatrix}, \begin{bmatrix} 0.0314 & -0.0340 & 0.0234 \\ -0.0340 & 1.2805 & -0.1572 \\ 0.0234 & -0.1572 & 0.1210 \end{bmatrix} \right) \).

In absence of environmental variables, inefficiencies are added so that \( y = y^\star \theta^o, 0 < \theta^o \leq 1 \) (Kneip et al. (2011); Badin and Simar (2003); Simar and Wilson (2002); Simar and Wilson (2000b); Resti (2000); Kit-

\(^4\)Therefore, papers that estimate input-oriented efficiency scores using input costs as inputs and interpret the scores as cost efficiency (Medin et al. (2011); Linna et al. (2010); Barros and Dieke (2008)) in fact, measure Tone (2002) “new” cost efficiency.
they. Simar and Wilson (2007), we set DGP compared to \( \rho \) where

\[
\beta = \frac{\sum_{n=1}^{N} \sum_{m=1}^{M} (y_m^{1/\rho_m} / A_m) \alpha_{nm} T_m \eta_m + \sum_{m=1}^{M} (y_m^{1/\rho_m} / A_m) \alpha_{Nnm} T_m \prod_{n=1}^{N-1} \eta_{nm}^{-(\alpha_{nm}/\alpha_N)}}{\sum_{n=1}^{N-1} \alpha_n \eta_n + \alpha_N \prod_{n=1}^{N-1} \eta_n^{-(\alpha_n/\alpha_N)}}
\]

where \( \rho_m = \sum_{n=1}^{N} \alpha_{nm} \) and \( T_m = \prod_{n=1}^{N} \left( \frac{w_n}{\alpha_{nm}} \right)^{\alpha_{nm}/\rho_m} \). Under \( \alpha_{nm} \equiv \alpha_n \) and \( \eta_{nm} \equiv \eta_n \) we obtain (eq.A.15):

\[
\gamma = \frac{\sum_{n=1}^{N-1} \alpha_n \eta_n + \alpha_N \prod_{n=1}^{N-1} \eta_n^{-(\alpha_n/\alpha_N)}}{\sum_{n=1}^{N-1} \alpha_n \eta_n + \alpha_N \prod_{n=1}^{N-1} \eta_n^{-(\alpha_n/\alpha_N)}}
\]

We use constant returns to scale \((\alpha_1, \alpha_2, \alpha_3) = (0.05, 0.05, 0.9)\). Cost inefficiencies are added to \( x_2 \) and \( x_3 \), and analytically computed for \( x_1 \). Regarding input-oriented efficiency, \( \theta = 1/(1 + \zeta) \), where \( \zeta \) is drawn from \( \text{Exp}(2) \) and \( E(\zeta) = 0.5 \). Note that \( 1 + \text{Exp}(2) \) has high probability of obtaining a point in the neighborhood of unity. Consequently, the DGP with exponential distribution allows easier estimation of the frontier if compared to DGPs with fewer points in the proximity of unity.\(^5\)

In presence of environmental variables, we introduce inefficiencies as \( y = y^* \delta^{-\rho}, 0 < \delta^{-\rho} \leq 1 \), where \( \delta \) can be expressed as \( \zeta \beta + \varepsilon \). We assume a simplified case when the lists of environmental variables, influencing input-oriented efficiency and cost efficiency coincide, \( \delta \sim N(\mu_{\zeta}, \sigma^2_{\zeta}) \) with left truncation at unity. Following Simar and Wilson (2007), we set \( r = 2, \beta_1 = \beta_2 = 0.5, z_1 = 1, z_2 \sim N(2, 4), \varepsilon \sim N(0, 1) \) with left-truncation at \( (1 - \zeta \beta) \), \( \delta = \zeta \beta + \varepsilon \). Then eq.(10) modifies to

\[
\delta^\gamma(z) = \frac{\delta}{\rho} \left( \sum_{n=1}^{N-1} \alpha_n \eta_n + \alpha_N \prod_{n=1}^{N-1} \eta_n^{-(\alpha_n/\alpha_N)} \right)
\]

As regards cost efficiency, \( \eta_n = e^{\nu_n} \), where \( \nu_n \sim N(0, \sigma^2_{\nu}) \). In this case the realized value of \( \eta_n \) may be smaller or larger than unity, and it allows to move \( x^* \) in different directions along the isouquant. To model different size of cost inefficiencies, we take \( \sigma_{\nu} = \{0.05, 0.1\} \).

Following Simar and Wilson (2011b), Kneip et al. (2008) and Simar and Wilson (2000b) we use 1000 trials with B=2000 iterations on each trial and samples \( J = \{50, 100, 200, 300, 400, 600, 800, 1000\} \). For each \( \alpha \in \{0.01, 0.05, 0.1\} \) we estimate probabilities of symmetric \((1 - \alpha)\) confidence intervals to cover true values of cost efficiency \( \gamma (1/\delta^\gamma) \) in absence (presence) of environmental variables.

A fixed point to measure cost efficiency on each trial is constructed as follows. We take a vector in the middle of the output and price data and assign it input-oriented efficiency \( E \). So the coordinates of a point on the frontier are \( (x^*(|E|^\rho \mu_y, \mu_w), |E|^\rho \mu_y) \), where \( x^*(\cdot, \cdot) \) is an optimal demand function from eq.(A.2). Then, we introduce inefficiencies \( E \eta \) to \((N-1)\) input coordinates of the point, and analytically compute the values of \( N \)-th input coordinate according to eq.(A.5).

---

\(^5\)If data-generating process results in a small number of points in the proximity of unity, the consistent estimation of the frontier would require increasing sample size appreciably.
4.2 Results

Owing to potential problems of ignoring zero bound in implementing the Silverman (1986) reflection method with the input-oriented efficiency scores $\theta$ (Simar and Wilson (2000a)), the estimations are conducted in terms of the reciprocals $\delta = 1/\theta$. Accordingly: first, each point $\hat{\delta}_i \geq 1$ is reflected by its symmetric image $2 - \hat{\delta}_i \leq 1$; second, kernel density is estimated from the set of $2J$ points (Simar and Wilson (2008)). Since the choice of bandwidth may influence coverage probabilities for small samples (Simar and Wilson (2000b); Kneip et al. (2008)), the simulations in this paper exploit two types of bandwidths: 1) Silverman’s (1986) bandwidth for standard normal density function; 2) bandwidth, estimated with least-squares cross-validation and adjusted for sample size (Simar and Wilson (2008)).

The rule of thumb bandwidth, proportional to $J^{-1/(3(M+N+1))}$ in case of bootstrapping $\theta$ (Kneip et al. (2008)), is not exploited in our estimations for a few reasons. Firstly, it requires a choice of a factor of proportionality, which may be an additional research task in the analysis with the reciprocal of $\theta$. Secondly, it gives comparable results with cross-validation bandwidth for consistent bias correction of technical efficiency scores (Simar and Wilson (1998); Badin and Simar (2003); Simar and Wilson (2000b); Kneip et al. (2008)), and our simulations within cost-minimization framework in terms of $\theta$ show similar results on the coverage probabilities for both bandwidths.

The results of simulations in terms of coverage probability and bias of the estimate are similar across cases 1 and 2, so the analysis below presents the results for case 1. In absence of environmental variables (Figure 3) we discover that for a given type of bandwidth and given values $\alpha$ and sample size $J$, coverage probability of confidence intervals is higher for smaller cost inefficiency (in terms of $\sigma$). Cross-validation bandwidth gives coverage probabilities that do not depend on sample size and are in the range of (0.65, 0.91) for $\alpha < 0.1$. Silverman’s (1986) bandwidth provides for the worst results, proving inapplicability of normal reference rule. As for the simulation in presence of environmental variables, where estimation does not involve the use of bandwidths, coverage probability of confidence interval are higher and close to $1 - \alpha$ with $J > 600$. The absolute difference between the true and bias-corrected values of cost efficiency both in absence and presence of environmental variables is close to 0.04 with the smallest sample size ($J = 50$) and becomes less than 0.01 with $J > 600$.

---

Values of output and costs in case 1 are derived from the asset approach, which has been most prevalent in the applied Japanese literature.

5 Efficiency estimates for Japanese banks

5.1 Data

We use financial data for all Japanese banks in the fiscal year ending March 2010 (Nikkei Financial Quests). The data are supplemented with the variables on the number of employees, bank branches and bank charter from Interim Financial Statements of Japanese banks (Japanese Bankers Association). Regional (prefectural) variables come from Bank of Japan (deposits, vault cash, loans and bills discounted), Economic and Social Research Institute, Cabinet Office (gross domestic product and gross domestic product deflator), Ministry of Land, Infrastructure and Transport, and Japan Statistical Yearbook (price of commercial land site).

We use three input - two output model, where outputs are either performing loans and total securities (asset approach, e.g. Hori and Yoshida (1996); Fukuyama and Weber (2002); Barros et al. (2012)) or revenue from loans and revenue from other business activities (intermediation approach, e.g. Kasuya (1986); Fukuyama (1993); Fukuyama (1995); Takahashi (2000); Fukuyama and Weber (2010)) (Thanasoulis et al. (2008); Tortosa-Austria (2002)). In each model the inputs are labor (total employees), capital (premises, real estate and intangibles) and funds from customers (Kasuya (1986); Kasuya (1989); Fukuyama (1993); Fukuyama (1995); Hori and Yoshida (1996); McKillop et al. (1996); Glass et al. (1998); Fukuyama and Weber (2002); Miyakoshi and Tsukuda (2004); Fukuyama and Weber (2008); Barros et al. (2012)). The proxies for input prices are, respectively, personnel expenditure/total employees, capital expenditure/capital and fund-raising expenditure/funds from customers (Kasuya (1986); Kasuya (1989); McKillop et al. (1996); Fukuyama and Weber (2002)). The choice of inputs, outputs and prices follows the methodology of efficiency analysis in Japanese banking. Bank-level environmental variables include bank size and bank product diversity (Aly et al. (1990); Simar and Wilson (2007)), non-performing loan ratio (Berger and Mester (2003)). Prefecture-level environmental variables are real rate of growth of gross domestic product and commercial land price, share of monetary aggregate and loans in gross domestic product (Liu and Tone (2008)). We include dichotomous variables by bank charter (city bank, regional bank, regional second tier bank, trust bank, long-term credit bank). Bank holdings and financial groups are excluded from the analysis (Table 5). Albeit our sample presents the whole banking industry in Japan, its size is only 112. Yet, the results of our simulations with $J = 100$ demonstrate high coverage probabilities in case of cross-validation bandwidth and rule of thumb bandwidth.

---

7 The research was started during Besstreymannaya’s PhD study at Keio University in 2008–2010, under the MEXT scholarship.

8 Note that intermediation approach prevails in international literature (Fethi and Pasiouras (2010)), yet, asset approach is more spread in the analyses on Japanese banking.

5.2 Results

Estimations are conducted under variable returns to scale with B=2000. As rule of thumb bandwidth may be unstable with moderate samples in estimations without environmental variables, we exploit least squares cross-validation in the choice of bandwidth. We use $z_1 - z_4$ and $z_9 - z_{12}$ in estimations with environmental variables (the rest are omitted owing to multicollinearity). Table 6 presents the estimates of “naive” score $\hat{\gamma} (1/\hat{\delta}_{\gamma})$ and bias-corrected score $\hat{\hat{\gamma}} (1/\hat{\hat{\delta}}_{\gamma})$ for the models, corresponding to asset approach and intermediation approach. In each model mean bias-corrected score is lower than mean “naive” score, while standard deviation of “naive” and bias-corrected scores are close. Bias-corrected score is “to the left” (if compared to the range of “naive” score), and there are no exact unity values of bias-corrected cost efficiency. The mean value of cost efficiency is higher in the model with asset approach both in presence and in absence of environmental variables. Accounting for environmental variables leads to higher cost efficiency scores, if compared to corresponding models without environmental variables.

Quantile-quantile plots for $\hat{\gamma}$ and $\hat{\gamma} (1/\hat{\delta}_{\gamma} \text{ and } 1/\hat{\hat{\delta}}_{\gamma})$ allow visualizing the bias and its heterogeneity over observations. As may be inferred from Figures 5 - 6 the upward bias of $\hat{\gamma} (1/\hat{\delta}_{\gamma})$ does not vary appreciably with bank charter for cost efficiency score under asset approach. However, the heterogeneity depends on bank charter in the model with intermediation approach: the distance from the 45 degree line is the largest for national banks and trust banks. The bias and heterogeneity is larger in presence of environmental variables.
Figure 5: Quantile-quantile plots for models with asset approach (left) and intermediation approach (right) in absence of environmental variables

Figure 6: Quantile-quantile plots for models with asset approach (left) and intermediation approach (right) in presence of environmental variables
Figure 7 demonstrates re-ranking of banks according to their bias-corrected cost efficiency scores. Indeed, ordered according to monotonically increasing “naive” cost efficiency scores $\hat{\gamma}$ (green line), banks have non-monotonic bias-corrected cost efficiency scores $\hat{\tilde{\gamma}}$ (blue line).

Similarly, Figure 8 indicates re-ranking of banks according to their bias-corrected distance function scores $\hat{\delta}$.

6 Conclusion

The paper shows that a direct modification of Simar and Wilson (1998) (Simar and Wilson (2007)) methodology is inconsistent for correcting the bias of Fare et al. (1985) cost efficiency scores and proposes an alternative bootstrap algorithm for robust estimation. To approximate the bias of “naive” cost efficiency score, the proposed algorithm re-samples “naive” input-oriented efficiency scores, rescales original inputs to bring them to the frontier, and then re-estimates cost efficiency scores for the rescaled inputs. The results of the simulation analyses for multi-input multi-output Cobb-Douglas production function with correlated outputs, and correlated technical and cost efficiency, show consistency of the proposed algorithm in terms of coverage probability of Kneip et al. (2008) confidence intervals for true cost efficiency. Consistency generally holds even for small samples. An application of the algorithm to real data of 112 Japanese banks in the fiscal year 2009 demonstrates re-ranking of banks according to their bias-corrected cost efficiency scores, as well as shows heterogeneity of bias according to bank charter.

Appendix A Microeconomic framework

The Cobb-Douglas production function is taken in the form

\[ y_m = A_m \prod_{n=1}^{N} x^{\alpha_{nm}}_m, \quad (A.1) \]

where \( x_{nm} \) is the quantity of \( n \)-th input, used to produce \( m \)-th output (\( x_n = \sum_{m=1}^{M} x_{nm} \), Resti (2000)). \( A_m \) and \( \alpha_{nm} \) are corresponding parameters.

The derived optimal demand for \( x^*_nm \) becomes a function of outputs and input prices (Shephard (1981); Resti (2000)):

\[ x^*_nm = \frac{(y^*_m/A_m)^{1/\sum_{n=1}^{N} \alpha_{nm}}} {\prod_{n=1}^{N} \alpha_{nm}/\sum_{n=1}^{N} \alpha_{nm}} \frac{\prod_{n=1}^{N} w_n^{\alpha_{nm}/\sum_{n=1}^{N} \alpha_{nm}}}{w_n^{\alpha_{nm}/\sum_{n=1}^{N} \alpha_{nm}}} T_m, \quad (A.2) \]

where \( \rho_m = \sum_{n=1}^{N} \alpha_{nm} \) and \( T_m = \prod_{n=1}^{N} \left( \frac{w_n^{\alpha_{nm}/\rho_m}}{\alpha_{nm}/\sum_{n=1}^{N} \alpha_{nm}} \right) \).

Cost inefficiency is added to \( (N-1) \) inputs, and then the value of the \( N \)-th input is computed, so that the the level of input-oriented efficiency for each DMU did not change (Resti (2000)). More formally,

\[ x_{nm} = x^*_nm \eta_{nm}, n = 1, \ldots, N - 1, \eta_{nm} > 0 \quad (A.3) \]

\[ x_{Nm} = \left( \frac{y^*_m}{A_m \prod_{n=1}^{N-1} x^*_nm^{\alpha_{nm}}} \right)^{1/\alpha_{Nm}}, \quad (A.4) \]

Substituting \( y^*_m \) in (A.4) by \( A_m \prod_{n=1}^{N} x^*_nm^{\alpha_{nm}} \), and for each \( n < N - 1 \) replacing \( x_{nm} \) by \( x^*_nm \eta_{nm} \), we obtain

\[ x_{Nm} = \left( \frac{y^*_m}{A_m \prod_{n=1}^{N-1} x^*_nm^{\alpha_{nm}}} \right)^{1/\alpha_{Nm}} = x^*_Nm \prod_{n=1}^{N-1} \eta_{nm}^{-\alpha_{nm}/\alpha_{Nm}} \quad (A.5) \]
The cost efficiency is (index \( j \) in \( \gamma \) omitted for simplicity):

\[
\gamma = \frac{wx^{opt}}{wx} = \frac{\sum_{n=1}^{N} x_n^{opt} w_n}{\sum_{n=1}^{N} x_n w_n}
\]  
(A.6)

As regards computing the denominator, the expressions for \( x_{nm} \) from (A.3) and (A.5) allow obtaining:

\[
x_n w_n = w_n \sum_{m=1}^{M} x_{nm} \eta_{nm}, n = 1, ..., N - 1
\]  
(A.7)

\[
x_N w_N = w_N \sum_{m=1}^{M} \prod_{n=1}^{N-1} \eta_{nm}/\alpha_{Nm}
\]  
(A.8)

Using (A.2) and (A.4) we express each \( x_n^{*} \) in terms of \( y_m \), so the total cost in a given point \((x, y)\) becomes:

\[
\sum_{n=1}^{N} x_n w_n = \sum_{n=1}^{N-1} \sum_{m=1}^{M} (y_m^{*}/A_m)^{1/\rho} \alpha_{nm} T_m \eta_{nm} + \sum_{m=1}^{M} (y_m^{*}/A_m)^{1/\rho} \alpha_{Nm} T_m \prod_{n=1}^{N-1} \eta_{nm}/\alpha_{Nm}
\]  
(A.9)

To calculate the nominator of (A.6), we use (A.2) to express \( x_n^{opt} \) in terms of \( y_m \):

\[
x_n^{opt} w_n = \sum_{m=1}^{M} (y_m^{*}/A_m)^{1/\rho} \alpha_{nm} T_m
\]  
(A.10)

Then,

\[
\sum_{n=1}^{N} x_n^{opt} w_n = \sum_{n=1}^{N-1} \sum_{m=1}^{M} (y_m^{*}/A_m)^{1/\rho} \alpha_{nm} T_m
\]  
(A.11)

Finally, since \( y_m = y_m^{\theta} \rho \), we can rewrite

\[
\sum_{n=1}^{N} x_n^{opt} w_n = \sum_{n=1}^{N-1} \sum_{m=1}^{M} (y_m^{*}/A_m)^{1/\rho} \theta \alpha_{nm} T_m
\]  
(A.12)

Then, cost efficiency \( \gamma \) is calculated as follows:

\[
\gamma = \frac{wx^{opt}}{wx} = \frac{\sum_{n=1}^{N} \sum_{m=1}^{M} (y_m^{*}/A_m)^{1/\rho} \theta \alpha_{nm} T_m}{\sum_{n=1}^{N-1} \sum_{m=1}^{M} (y_m^{*}/A_m)^{1/\rho} \alpha_{nm} T_m \eta_{nm} + \sum_{m=1}^{M} (y_m^{*}/A_m)^{1/\rho} \alpha_{Nm} T_m \prod_{n=1}^{N-1} \eta_{nm}/\alpha_{Nm}}
\]  
(A.13)

Both our estimations with Japanese data and the results in the empirical literature (Liu et al. (2012); Wang (2003); Banker et al. (1993); Giokas (1991)) show that input elasticities do not vary appreciably for banking outputs, employed in this paper. Therefore, we impose a simplifying assumption \( \alpha_{nm} = \alpha_n \), which leads to \( T_m = T \) and \( \rho_m = \rho \). Accordingly, it becomes reasonable to add inefficiencies to inputs, so that \( \eta_{nm} = \eta_n \). The assumptions allow computing cost efficiency \( \gamma \) as follows:

\[
\gamma = \frac{T \theta \sum_{n=1}^{N} \alpha_n \sum_{m=1}^{M} (y_m^{*}/A_m)^{1/\rho}}{\sum_{n=1}^{N-1} \alpha_n \eta_n \sum_{m=1}^{M} (y_m^{*}/A_m)^{1/\rho} + T \alpha_N \prod_{n=1}^{N-1} \eta_n \sum_{m=1}^{M} (y_m^{*}/A_m)^{1/\rho}}
\]  
(A.14)
Canceling $T$ and $\sum_{m=1}^{M} (y_m^*/A_m)^{1/\rho}$ leads to:

$$\gamma = \frac{\theta \sum_{n=1}^{N} \alpha_n}{\sum_{n=1}^{N-1} \alpha_n \eta_n + \alpha_N \prod_{n=1}^{N-1} \eta_n} \frac{-\alpha_n/\alpha_N}{(\ref{A.15})}$$
